ABSTRACT

In this paper we have made an attempt to derive the radial profiles of density and temperature of intracluster gas based on the two well-established facts at present: the X-ray observed surface brightness of clusters described by the standard β model and the (NFW) universal density profile as the underlying dark matter distribution. We have numerically solved the hydrostatic equation by demanding that the volumed-averaged baryon fraction of a cluster should asymptotically approach the universal value at its virial radius. We have shown that the radial temperature variation derived from these constraints differs significantly from the conventional polytropic equation of state: The gas temperature profile may show a dramatic increase or decrease with outward radius, depending sensitively on the β parameter. A large β value (typically > 0.8) is required in order to ensure that the X-ray temperature makes a drop at the virial radius. This indicates that either the NFW profile is inappropriate to apply for the overall dark matter distribution of clusters or other non-gravitational heating processes may play an important role in the dynamical evolution of clusters.

Subject headings: cosmology: theory — dark matter — galaxies: clusters: general — X-rays: galaxies

1. INTRODUCTION

One of the major uncertainties in the cosmological applications of dynamical properties and evolution of galaxy clusters, e.g., the baryon fraction f_b and the X-ray luminosity-temperature correlation, has probably arisen from the poorly constrained radial variations of density and especially, temperature of hot intracluster gas. Indeed, the currently available X-ray spectral data of clusters in literature may have suffered various instrumental limitations (see, for example, Irwin, Bregman & Evrard 1999), and even conflicting results regarding the radial temperature gradients can be obtained by different authors based on different analysis techniques (e.g. Markevitch et al. 1998; Irwin et al. 1999; White 2000; Irwin & Bregman 2000). This leads to an embarrassing situation that an oversimplified, isothermal gas distribution is often adopted in the estimate of the total gravitating mass $M_{\text{tot}}(r)$ of a cluster enclosed within radius r via the hydrostatic equilibrium hypothesis. Here, it is worthy of mentioning another possibility of obtaining the radial distribution of intracluster gas in an indirect way, namely, by the inversion of the X-ray and S-Z observed surface brightness profiles of clusters (Silk & White 1978; Yoshikawa & Suto 1999). Yet, the actual application of this technique to clusters is still limited primarily by the current S-Z measurements.

Several efforts have thus been made towards deriving the radial profiles of density and temperature of intracluster gas based on the well-motivated physical mechanisms. Among these the shape of the gas density distribution following the universal density profile of the dark matter halos of clusters suggested by numerical simulations (Navarro, Frenk & White 1995; NFW) has received great interest (e.g. Makino, Sasaki & Suto 1998; Ettori & Fabian 1999; Wu & Xue 2000a; Wu 2000; etc.). While its inner and outer slopes are still under debate, the NFW profile may be considered to be a good approximation of the matter distribution of dark halos. Alternatively, a number of high-resolution simulations have also

shown that the NFW profile is independent of mass, the initial density fluctuation, and the cosmology (Cole & Lacey 1996; Navarro, Frenk & White 1997; Eke, Navarro & Frenk 1998). Indeed, within the framework of isothermal and hydrostatic equilibrium there is a striking similarity between the gas density distribution predicted by the NFW profile and the conventional β model revealed by the X-ray observations (Makino et al. 1998). Inclusion of the self-gravity of the gas and the polytropic equation of state makes it promising to directly link the theoretical predictions with the actual X-ray observations of clusters (Suto, Sasaki & Makino 1998).

Here, we view the problem from a different angle: Given (1) the radial variation of the dark matter particles characterized by the NFW profile and (2) the X-ray observed surface brightness profiles of clusters, what can we learn about the radial density and temperature profiles of the intracluster gas? Namely, we begin with the two well-established ‘observational’ facts today, and drop the assumption about the temperature properties of the gas (isothermal or polytropic). Nevertheless, we include the self-gravity of the gas. We then solve the hydrostatic equation with the following boundary constraint: The volume-averaged baryon fraction $f_b(r)$ within the virial radius r_{vir} should asymptotically approach a universal value $f_{b,\text{BBN}} \equiv \Omega_b/\Omega_m$ defined by the Big Bang Nucleosynthesis, where Ω_b and Ω_m are the average baryon and total mass densities of the Universe in units of the critical density ρ_{crit} for closure, respectively. The reasons why we impose this condition on the solution are as follows: First, it is generally believed that the matter composition of clusters averaged over a sufficiently large volume should be representative of the Universe. Second, the present X-ray observations have revealed an increase in the baryon fraction of clusters with radii and no evidence for an asymptotic tendency towards a universal value at large radii (White & Fabian 1995; David 1997; White, Jones & Forman 1997; Ettori & Fabian 1999; Jones & Forman 1999; Markevitch et al. 1999). This conflict has probably arisen from the oversimplification of the currently adopted temperature model for the

intracluster gas. Setting a priori the universality of $f_b(r_{\text{vir}})$ can instead allow one to work out the constraints on the radial variations of density and temperature of the gas. Third, the boundary condition will be required mathematically in order to solve the hydrostatic equation, while little has been known about the gas properties within the central cores of clusters where the local dynamical activities may play a dominant role.

In a word, if the distribution of dark matter can be reasonably approximated by the NFW profile, we will be able to derive the radial density and temperature profiles of intracluster gas based on the well measured X-ray surface brightness of clusters with the constraint that the baryon fraction within the virial radius is universal. The resulting density and temperature profiles can be directly compared with the X-ray spectroscopic measurements and the S-Z observations of clusters, which will provide a critical test for the validity of the NFW profile and the hydrostatic equilibrium hypothesis. Meanwhile, such a study will be helpful for resolving the conflict regarding the different temperature measurements, i.e., whether or not the X-ray emitting gas can be regarded as isothermal in clusters. Eventually, we hope that this research will be of significance for our understanding of the fundamental physical processes in the dynamical evolution of clusters including non-gravitational heating.

2. THE MODEL

We assume that the dark halo of a cluster is described by the NFW profile

$$\rho_{\text{DM}}(r) = \frac{\rho_s}{(r/r_s)(1 + r/r_s)^2}, \quad (1)$$

where ρ_s and r_s are the characteristic density and length, respectively. Another two equivalent parameters frequently used in literature are $\delta_c \equiv \rho_s/\rho_{\text{crit}}$ and $c \equiv r_{\text{vir}}/r_s$. The

virial radius r_{vir} is defined by

$$M_{\text{DM}}(r_{\text{vir}}) = \frac{4\pi}{3} r_{\text{vir}}^3 \Delta_{\text{c}} \rho_{\text{crit}}, \quad (2)$$

where Δ_{c} represents the overdensity of dark matter with respect to the average background value ρ_{crit} , for which we will take $\Delta_{\text{c}} = 200$ in the following computation. Our main conclusion is unaffected by this choice. The total mass of the dark matter halo enclosed within radius r is

$$M_{\text{DM}}(r) = 4\pi \rho_{\text{s}} r_{\text{s}}^3 \left[\ln \left(1 + \frac{r}{r_{\text{s}}} \right) - \frac{r}{r + r_{\text{s}}} \right]. \quad (3)$$

On the other hand, the X-ray surface brightness profile $S_{\text{x}}(r)$ can be approximated by the conventional β model:

$$S_{\text{x}}(r) = S_0 \left(1 + \frac{r^2}{r_{\text{c}}^2} \right)^{-3\beta+1/2}, \quad (4)$$

in which r_{c} denotes the core radius. For the thermal bremsstrahlung emission, the above form of $S_{\text{x}}(r)$ indicates (Cowie, Henriksen & Mushotzky 1987)

$$n_{\text{gas}}(r) T^{1/4}(r) = n_{\text{gas},0} T_0^{1/4} \left(1 + \frac{r^2}{r_{\text{c}}^2} \right)^{-3\beta/2}, \quad (5)$$

where n_{gas} and T are the gas number density and temperature, respectively. Equation (5) identifies the β density profile in the case of isothermality. As a result, the total mass in gas within r is simply

$$M_{\text{gas}}(r) = 4\pi \mu m_{\text{p}} n_{\text{gas},0} \int \left(\frac{T_0}{T} \right)^{1/4} \left(1 + \frac{r^2}{r_{\text{c}}^2} \right)^{-3\beta/2} r^2 dr, \quad (6)$$

in which $\mu = 0.585$ is the average molecular weight. The volume-averaged baryon fraction $f_{\text{b}}(r)$ within r is defined as

$$f_{\text{b}}(r) = \frac{M_{\text{gas}}(r)}{M_{\text{gas}}(r) + M_{\text{DM}}(r)}. \quad (7)$$

Here we have neglected the contribution of stellar mass to $f_{\text{b}}(r)$. We further assume that the gas is in hydrostatic equilibrium with the underlying gravitational potential of the

cluster produced by $M_{\text{tot}}(r) \equiv M_{\text{gas}}(r) + M_{\text{DM}}(r)$, i.e.,

$$\frac{G[M_{\text{gas}}(r) + M_{\text{DM}}(r)]}{r^2} = -\frac{1}{\mu m_{\text{p}} n_{\text{gas}}} \frac{d(n_{\text{gas}} kT)}{dr}. \quad (8)$$

Using temperature and baryon fraction as the two variables and re-organizing the above equations yield

$$\frac{d\tilde{T}}{dx} = \frac{4\beta x \tilde{T}}{x^2 + a^2} - \frac{4\alpha_0}{3x^2} \left[\ln(1+x) - \frac{x}{1+x} \right] \frac{1}{1-f_{\text{b}}}, \quad (9)$$

$$\frac{df_{\text{b}}}{dx} = \frac{(1-f_{\text{b}})^2 b \tilde{T}^{-\frac{1}{4}} (1 + \frac{x^2}{a^2})^{-\frac{3\beta}{2}} x^2 - f_{\text{b}}(1-f_{\text{b}}) \frac{x}{(1+x)^2}}{\ln(1+x) - \frac{x}{1+x}}, \quad (10)$$

in which the scaled quantities are: $\tilde{T} = T/T_0$, $x = r/r_{\text{s}}$, $a = r_{\text{c}}/r_{\text{s}}$, $b = \mu m_{\text{p}} n_{\text{gas},0}/\rho_{\text{s}}$, and $\alpha_0 = 4\pi G \mu m_{\text{p}} \rho_{\text{s}} r_{\text{s}}^2 / kT_0$. Our task is thus reduced to finding the solutions of equations (9) and (10) with the following boundary conditions

$$\tilde{T}(0) = 1, \quad (11)$$

and

$$f_{\text{b}}(c) = f_{\text{b,BBN}}; \quad (12)$$

$$\left. \frac{df_{\text{b}}}{dx} \right|_{x=c} = 0. \quad (13)$$

This last constraint demands that the baryon fraction should asymptotically match the universal value of $f_{\text{b,BBN}}$ at the virial radius r_{vir} or equivalently c .

3. RESULTS

3.1. General properties

There are a total of five parameters involved in equations (9) and (10): β , α_0 , a , b and δ_{c} or c . Additionally, the universal baryon fraction $f_{\text{b,BBN}}$ should also be regarded as

another unknown parameter although Ω_b has been fixed by the Big Bang Nucleosynthesis. However, these parameters are not independent, as we will discuss in some detail later. Mathematically, the number of these free parameters can be reduced by two with the restriction of the two first-order differential equations, equations (9) and (10), and the associated boundary conditions. Namely, given four of the six parameters (β , α_0 , a , b , δ_c , $f_{b,\text{BBN}}$), we will be able to find the other two from equations (9) and (10). Technically, we perform iteratively the numerical searches for the solutions of equations (9) and (10) over a space of two parameters until the boundary conditions equations (11)-(13) are satisfied. Using the resultant temperature $\tilde{T}$, we will then derive the scaled gas density $\tilde{n}_{\text{gas}} \equiv n_{\text{gas}}(r)/n_{\text{gas},0}$ according to equation (5):

$$\tilde{n}_{\text{gas}} = \tilde{T}^{-1/4} \left(1 + \frac{r^2}{r_c^2} \right)^{-3\beta/2}. \quad (14)$$

We demonstrate in Figure 1 a set of typical solutions for $a = 0.3$, $\delta_c = 10^4$ and $f_{b,\text{BBN}} = 0.1$ but with different choices of β : $2/3$, 0.75 , 0.85 and 1 . The other two parameters, b and α_0 , can be uniquely determined in each case during our numerical searches for the solutions, which read $(b, \alpha_0) = (0.34, 5.73)$, $(0.42, 6.22)$, $(0.65, 6.61)$ and $(1.34, 6.96)$ for $\beta = 2/3$, 0.75 , 0.85 and 1 , respectively. The halo concentration for our example is found to be $c = r_{\text{vir}}/r_s = 5.32$. We have also displayed in Figure 1 the input $S_x(r)$ and our derived radial profiles of gas density, $\tilde{n}_{\text{gas}}$.

EDITOR: PLACE FIGURE ?? HERE.

It is not surprising from Figure 1 that the shape of the resulting radial profiles of gas density, $\tilde{n}_{\text{gas}}$, is very similar to the conventional expectation, i.e., the β model. Alternatively, the baryon fraction $f_b(r)$ shows an increase with radius roughly within the core regions, and then asymptotically approaches the background value $f_{b,\text{BBN}}$ at virial radius c (for a small β) or reaches a maximum before it matches the background value (for a large β).

However, the temperature profile $\tilde{T}(r)$ derived from equations (9) and (10) along with the restrictions equations (11)–(13) exhibits a remarkable difference in the radial variation among different β clusters, from a rapid increase at large radii for a small β to a sharp drop near the virial radius for a large β , separated roughly at $\beta \approx 0.8$. This property is mainly due to our restriction on the baryon fraction at $x = c$ (equations [12] and [13]): $f_b = f_{b,\text{BBN}}$ and $df_b/dx = 0$. Recall that a similar temperature behavior is required in order for f_b to asymptotically approach the universal value $f_{b,\text{BBN}}$ at large radii within the framework of the β model and the hydrostatic equilibrium for intracluster gas, in which the separation of the two different variations of the asymptotic temperature at large radii occurs at $\beta = 2/3$ (Wu & Xue 2000b).

Similarly, we can numerically obtain the eigenvalues (α_0, b) for different choices of $(\beta, a, \delta_c, f_{b,\text{BBN}})$. In Figure 2 we display the dependence of the resultant eigenvalues (α_0, b) upon each of the four parameters. The most interesting result is the cut-off of β parameter set by $\alpha_0 = 0$, below which, the unphysical solutions will occur. This indicates that the observed X-ray surface brightness profile $S_x(r)$ described by the β model should not have too small values of β if our working scenario holds true. In order to demonstrate how the cut-off value, β_{cut} , varies with clusters, we perform a search for the solutions with $\alpha_0 = 0$. In this case, the eigenvalue b can be uniquely fixed by our numerical solutions. Meanwhile, our numerical search shows that $f_{b,\text{BBN}}$ produces a minor effect on β_{cut} . Consequently, β_{cut} depends mainly on two parameters: δ_c and a (Figure 3). It turns out that for a typical cluster with $\delta_c = 10^3$ – 10^5 and $a = 0.1$ – 1 , the β parameter should be greater than 0.5, and β_{cut} may exceed 0.6 if $\delta_c > 10^5$. These constraints on β parameter seem to be in good agreement with the X-ray observations that the majority of the X-ray clusters have X-ray surface brightness profiles that satisfy $\beta > 0.5$.

EDITOR: PLACE FIGURE ?? HERE.

Essentially, the parameter α_0 depends very weakly on δ_c , $f_{b,\text{BBN}}$ and β (for $\beta > \beta_{\text{cut}}$), and its typical values for $a = 0.15$ and 0.3 are around 10 and 6.5, respectively. Our estimates can be compared with the previous studies that assumed an isothermal gas distribution tracing the gravitational potential of the NFW profile but dropping the restrictions of equations (12)–(13): For rich clusters the variation of α_0 is limited to a very narrow range from 6 to 25 with an average value of ~ 10 (Ettori & Fabian 1999; Wu & Xue 2000a; Wu 2000). Actually, α_0 can be approximately regarded as a constant for a given a (see Figure 2).

3.2. Asymptotic temperature at large radii

We learn from Figure 1 that there exists a critical value of β_{crit} such that $\tilde{T}(c) = 1$. Namely, the radial temperature profile close to $x = c$ will show a tendency to increase (decrease) with radius when $\beta < \beta_{\text{crit}}$ ($\beta > \beta_{\text{crit}}$). The existence of such a β_{crit} can be understood qualitatively by considering the following limiting situation where the virial radius c is much greater than the gas core radius a . The universal profile admits an x^{-3} density at large x . If the distribution of $f_{b,\text{BBN}}$ is to be asymptotically flat, the gas density $\tilde{n}_{\text{gas}}$ must also obey x^{-3} at large x . Given that the β model requires equation (14) to hold, the existence of a β_{crit} thus naturally follows. For this limiting situation, $\beta_{\text{crit}} = 1$ but when c no longer significantly exceeds a , the value of β_{crit} is found to vary somewhat as described below.

While the asymptotic high-temperature and low-temperature are both allowed mathematically, there should be one temperature profile at large cluster radii. Indeed, it is very unlikely that the gas temperature would increase monotonically with outward radius. At least, there is no known mechanism that can produce a significant rise of gas temperature at outermost radii. Note that this does not exclude a mild increasing temperature with

radius over a certain region of clusters (e.g. Irwin & Bregman 2000). As a result, the condition $\tilde{T}(c) = 1$ sets another low limit on the value of β , which guarantees that the gas temperature would not rise at virial radius when $\beta > \beta_{\text{crit}}$.

In order to determine β_{crit} , we once again perform the numerical searches for the solutions of equations (9) and (10) with the additional constraint $\tilde{T}(c) = 1$. This last point reduces the free parameters to three: $f_{\text{b,BBN}}$, δ_c and a . In Figure 3 we plot the resulting β_{crit} against δ_c for two different choices of a ($a = 0.1$ and $a = 1$) but a fixed universal baryon fraction of $f_{\text{b,BBN}} = 0.1$. It appears that although β_{crit} shows a radial variation similar to that of β_{cut} , the value of β_{crit} is apparently larger than the corresponding result for β_{cut} , indicating that the observed X-ray surface brightness profiles of clusters should possess an even larger β parameter than β_{cut} to ensure the natural drop of gas temperature at the edges of clusters. For our examples shown in Figure 3, the β parameters are required to exceed 0.7 and 0.8 for $\delta_c = 10^3$ and 10^4 , respectively. This may constitute a critical test for the working hypotheses established in the above section. The currently available data from X-ray measurements seem to marginally agree with these limits even if the effect of cooling flows (e.g. Vikhlinin et al. 1999), and the unknown parameters (a , δ_c and $f_{\text{b,BBN}}$) are taken into account. We will explore in detail the possible reasons in the discussion section.

EDITOR: PLACE FIGURE ?? HERE.

3.3. Self-consistent solution

In an optically thin plasma emission model, the central gas density $n_{\text{gas},0}$ is related to the central surface brightness $S_x(0)$ through

$$n_{\text{gas},0}^2 = 4\pi^{1/2} \frac{1}{\bar{g}} \frac{1}{\bar{\mu} \alpha(T_0)} \frac{\Gamma(3\beta)}{\Gamma(3\beta - 1/2)} \frac{S_x(0)}{r_c}, \quad (15)$$

where $\alpha(T_0)$ is the cooling function

$$\alpha(T_0) = \left(\frac{2^4 e^6}{3 m_e \hbar c^2} \right) \left(\frac{2 \pi k T_0}{3 m_e c^2} \right)^{1/2}, \quad (16)$$

$\bar{g}$ is the average Gaunt factor and $\bar{\mu} \equiv \mu^2(1 + X)/2$ with $X = 0.768$ being the primordial hydrogen mass fraction. The X-ray measurement of the surface brightness profile of a cluster provides us with the following quantities, $S_x(0)$, β and r_c . On the other hand, the central electron temperature T_0 , can be obtained relatively easily by the X-ray spectroscopic measurements, as compared with the outermost temperature, e.g. $T(x \approx c)$. Given $S_x(0)$, β , r_c and T_0 , we will be able to derive the central gas density $n_{\text{gas},0}$ in terms of equations (15) and (16). Moreover, since the purpose of the present paper is not to estimate the baryon fraction of clusters, we assume that the universal value of $f_{\text{b,BBN}}$ is known. As a result, there are only two parameters, ρ_s (or equivalently δ_c) and r_s in the NFW profile, that remain to be determined. We thus search for the solutions of equations (9) and (10) by iterations with a set of (δ_c, a) until a self-consistent solution is achieved, which uniquely determines the parameters δ_c and r_s in the NFW profile. Recall that in the isothermal case, the X-ray surface brightness profile predicted by the NFW profile is directly applicable to the fitting of the observed $S_x(r)$, giving rise to the two parameters, δ_c and r_s (Makino et al. 1998; Ettori & Fabian 1999; Wu & Xue 2000a,c; Wu 2000). Indeed, it appears that the procedure of finding the two parameters in the NFW profile now becomes very complicated if the temperature profile of a cluster is unknown.

In the present paper we do not intend to determine the parameters (ρ_s, r_s) by applying the current method to an ensemble of X-ray clusters. Instead, we present the result for a typical cluster with $n_{\text{gas},0} = 5 \times 10^{-3} \text{ cm}^{-3}$, $r_c = 0.25 \text{ Mpc}$ ($H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$) and $T_0 = 7 \text{ keV}$ but different β parameters. We fix the universal baryon fraction to be $f_{\text{b,BBN}} = 0.1$. The resulting ρ_s and r_s , along with the concentration parameter c (or equivalently, the virial radius) and the corresponding temperature $\tilde{T}(c)$ at $x = c$, are listed

in Table 1. Apart from the significant differences in the outermost temperatures at virial radii for different β parameters, the values of the remaining parameters, r_s , δ_c and c , all fall inside the limits for typical rich clusters with an isothermal gas distribution (Ettori & Fabian 1999; Wu & Xue 2000a,c; Wu 2000). This implies, on the other hand, that the determination of the two parameters in the NFW profile from the X-ray observations of intracluster gas is probably insensitive to the radial temperature variations. However, the temperature rise or drop near the edge of a cluster depends critically on the β parameter.

4. DISCUSSION AND CONCLUSIONS

The current X-ray measurements of the radial temperature profiles of intracluster gas especially at outer radii have some ambiguity, which is probably responsible for the major uncertainties in the present determination of the gravitating masses of clusters. Additionally, the large dispersion of the derived baryon fraction among different clusters may be also associated with the poorly constrained cluster temperatures. Consequently, the cosmological application of the dynamical properties of clusters are significantly affected. In the absence of a reliable constraint on the radial temperature variation from X-ray spectral measurements, we have made an attempt in the present paper to derive the temperature profile $T(r)$ based on the well-established facts from the X-ray observations and numerical simulations, along with some plausible boundary conditions. Specifically, we use the NFW profile as the dark matter distribution $n_{\text{DM}}(r)$ of clusters, and assume that intracluster gas $n_{\text{gas}}(r)$ is in hydrostatic equilibrium with the underlying gravitational potential dominated by $n_{\text{DM}}(r)$ and $n_{\text{gas}}(r)$. We adopt the X-ray observed surface brightness profile $S_x(r)$ described by the conventional β model to set up a link between gas density $n_{\text{gas}}(r)$ and temperature $T(r)$. We have then numerically solved the hydrostatic equation by demanding that the baryon fraction $f_b(r)$ approaches asymptotically the universal value

$f_{\text{b,BBN}} = \Omega_{\text{b}}/\Omega_{\text{M}}$ at the viral radius. As a result, we can simultaneously determine the radial profiles of gas density, temperature and baryon fraction in clusters. In particular, using the X-ray data of β , r_{c} , $S_{\text{x}}(0)$ and T_0 , we are able to find the two free parameters in the NFW profile, with which the dark matter profile can be completely fixed.

The temperature profile constructed jointly from the NFW profile and the X-ray surface brightness measurement appears to be significantly different from the conventional speculation. Apparently, our temperature profiles (see Figure 1) cannot be simply described by the widely adopted polytropic equation of state, $T \propto n_{\text{gas}}^{\gamma-1}$ where γ is the polytropic index, which is reflected by the striking difference between the core radius of gas density and that of temperature. It seems that the shape of temperature profiles in the outer regions of clusters can be dramatically different, depending sensitively on the β parameter. This point has mainly arisen from the restriction that the volume-averaged baryon fraction should asymptotically approach the universal value at the virial radius. The recent study by Wu & Xue (2000b) based on the β model and the polytropic gas distribution has essentially reached a similar result, i.e. a mild increase in temperature with radius should be required for clusters with $1/3 < \beta < 2/3$ in order to ensure the universal constancy of the cluster baryon fraction at large radii. Although this possibility has been reported for some clusters by Irwin & Bregman (2000) and shown in Figure 1 for small β (more clearly Figure 4 for $\beta = 2/3$), naturally we would expect a drop in temperature at the outermost radii. This can be achieved if the β parameters become larger (typically $\beta > 0.8$). While numerical studies of cluster formation and evolution often yield a similar result of $\beta \approx 0.7$ –1, observationally, it is unlikely that one can significantly raise the β value to $\beta > 0.8$ from the fitting of the X-ray surface brightness profiles of clusters. Exclusion of the central cooling regions or employment of the double β models in the fitting of the observed $S_{\text{x}}(r)$ can only lead to a moderate increase of the β parameter (e.g. Jones & Forman 1984; Vikhlinin et al. 1999; Xue & Wu 2000a).

In addition to the X-ray spectroscopic measurements, the SZ effect may also help to make a distinction between the temperature rise or fall models at large radii close to r_{vir} . The SZ effect depends on the gas density and temperature via $\Delta T/T_{\text{CBR}} \propto \int n_{\text{gas}} T d\ell$, where T_{CBR} represents the temperature of the cosmic background radiation, and the integral is performed along the line of sight ℓ . In Figure 4 we demonstrate the thermal SZ effect produced by two clusters with $\beta = 2/3$ and 1, respectively, adopting the same parameters as in Figure 1. If the gas temperature shows a dramatic increase with radius, the shape of the SZ profile will be strongly distorted. On the contrary, it turns out to be hard to distinguish the temperature decreasing model from the isothermal one simply based on the SZ observations.

EDITOR: PLACE FIGURE ?? HERE.

Although we have fulfilled our task that the radial profiles of density and temperature of intracluster gas are derived from the well-established facts, the existing X-ray data and future X-ray observations can provide a critical test of these predictions. Any conflict between observations and our predictions would imply that at least one of the following working hypotheses should be abandoned: (1) the NFW profile as the dark matter distribution of clusters; (2) the hydrostatic equilibrium for intracluster gas; (3) the pure thermal bremsstrahlung as the observed X-ray emission; and (4) the total baryon fraction of clusters as a reliable indicator of matter mixture of the Universe. In fact, all these hypotheses have been challenged in recent years.

It has been noticed that the central cusp in the NFW profile disagrees with the soft inner mass distributions of galaxies and clusters, which has led Spergel & Steinhardt (2000) to propose the possibility that the cold dark matter particles are self-interacting. Indeed, the X-ray surface brightness of clusters predicted from the NFW profile has a much smaller

core radius than the one seen from X-ray observations (Makino et al. 1998). In fact, the cusped NFW profile yields a higher central gas temperature, which can be clearly seen from the temperature profiles plotted linearly in Figure 4, while the X-ray spectroscopic measurements often reveal a cold gas component inside the core regions. As a result, a modification to the NFW profile should be properly made, such as the empirical density profile with a definite core radius $\rho_{\text{DM}} = \rho_0(1+x)^{-1}(1+x^2)^{-1}$ (Burkert 1995), which may both provide a good fit to the dark matter distribution and predict the right shape of the X-ray surface brightness distribution of clusters (Wu & Xue 2000c). However, fitting the predicted X-ray surface brightness profiles by such a revised dark halo profile to an ensemble of the X-ray observed surface brightness profiles of clusters, Wu & Xue (2000c) have shown that the core radii of the dark matter halos reach the X-ray core sizes of ~ 0.2 Mpc. The recent numerical simulations under some simple models for self-interacting dark matter particles have essentially arrived at the similar conclusion (Yoshida et al. 2000). Such large dark matter cores apparently exceed the ones required by modeling giant arcs seen in the central regions of clusters (Hammer 1991; Wu & Hammer 1993; Grossman & Saha 1994; Tyson et al. 1998). In a sense, any attempts at significantly modifying the NFW profile may require novel physical mechanisms.

Alternatively, it has been argued in recent years whether the intracluster gas is in perfect hydrostatic equilibrium with the underlying gravitational potential, based mainly on the presence of substructures and complex temperature patterns in clusters revealed by optical/X-ray observations (e.g. Henriksen & White 1996; Markevitch 1996). Yet, a statistical comparison of cluster masses derived from optical/X-ray observations and the NFW profile, under the assumption of hydrostatic equilibrium, and the strong/weak gravitational lensing measurements shows excellent agreement among different cluster mass estimates on scales greater than the X-ray core radii (Allen 1998; Wu et al. 1998; Wu 2000; references therein). This suggests that the hydrostatic equilibrium may break down only

on small scales where the local dynamical activities make a non-negligible contribution to cluster mass estimates, and hydrostatic equilibrium can be reasonably applicable to the overall distribution of intracluster gas.

Our emphasis is thus laid on the effect of non-gravitational heating processes in the dynamical evolution of clusters. It has been known in the past years that the observationally determined X-ray luminosity (L_x) and temperature relation, $L_x \propto T^3$, deviates significantly from the prediction, $L_x \propto T^2$, under the standard scenario that assumes the hydrostatic equilibrium and the thermal bremsstrahlung emission for intracluster gas (e.g. David et al. 1993; Markevitch 1998). While one cannot definitely exclude the possibility that the baryon fraction of clusters may vary with temperature (David et al. 1993), this conflict is strongly suggestive of the importance of the non-gravitational heating processes in the cosmic evolution of clusters. In fact, supernovae in cluster galaxies would substantially inject energy into intracluster medium through galactic winds in the early phase of cluster formation, and the intracluster gas can be heated to temperatures even exceeding that produced by gravitational heating alone (White 1991; David, Forman & Jones 1991). This scenario may allow one to reproduce naturally the observed L_x - T relation $L_x \propto T^3$ (Ponman, Cannon & Navarro 1999; Wu, Fabian & Nulsen 1999; Loewenstein 2000). In particular, the energy input from supernova-driven protogalactic winds will permit the intracluster gas to extend out to larger radii, giving rise to a shallower X-ray surface brightness profile (David et al. 1990; Ponman et al. 1999; Lloyd-Davies, Ponman & Cannon 2000). The discrepancy between the large β parameters ($\beta > 0.8$) required to maintain the decreasing temperature profile near virial radius discussed in the present paper and the relatively small value of $\beta \approx 0.7$ found from the X-ray observed surface brightness profiles of clusters is probably due to our negligence of the effect of other heating processes. A reliable construction of the radial density and temperature profiles of intracluster gas should also allow the non-gravitational heating to be included.

Taking these arguments as a whole, we feel that the exercise made in this paper, combined with the X-ray observations of clusters, will be helpful for our understanding of the fundamental physical process that dominates the dynamical evolution of clusters. Applications of the current method to real X-ray clusters will be presented in subsequent work (Xue & Wu 2000b).

Table 1: δ_c and r_s for a typical cluster^a

β	r_s (Mpc)	δ_c	c	$\tilde{T}(c)$
0.70	0.51	7051	4.54	4.66
0.75	0.49	7314	4.63	2.56
0.80	0.41	8068	4.84	2.00
0.85	0.39	8600	4.98	0.77
1.00	0.29	11000	5.54	0.06

^a $T_0 = 7$ keV, $r_c = 0.25$ Mpc and $n_{\text{gas},0} = 5 \times 10^{-3} \text{ cm}^{-3}$.

Fig. 1.— The derived radial profiles of gas density ($n_{\text{gas}}/n_{\text{gas},0}$), temperature (T/T_0) and baryon fraction (f_b) for $f_{b,\text{BBN}} = 0.1$, $a = r_c/r_s = 0.3$ and $\delta_c = \rho_s/\rho_{\text{crit}} = 10^4$ but with four different choices of β . Also shown are the input X-ray surface brightness profiles of clusters described by the conventional β model. The dotted line denotes the virial radius.

Fig. 2.— Dependence of $\alpha_0 (= 4\pi G \mu m_p \rho_s r_s^2 / k T_0)$ (dotted lines) and $b (= \mu m_p n_{\text{gas},0} / \rho_s)$ (solid lines) on (1) β ($\delta_c = 10^4$, $a = 0.3$ and $f_{b,\text{BBN}} = 0.1$), (2) $f_{b,\text{BBN}}$ ($\beta = 0.75$, $\delta_c = 10^4$ and $a = 0.3$), (3) δ_c ($\beta = 0.75$, $a = 0.3$ and $f_{b,\text{BBN}} = 0.1$), and (4) a ($\beta = 0.75$, $\delta_c = 10^4$, and $f_{b,\text{BBN}} = 0.1$).

Fig. 3.— Lower limits on β parameter against the characteristic density δ_c for two choices of a : (1) $a = 0.1$ (solid line and open squares) and (2) $a = 1$ (dashed line and open circles). Solid and dashed lines: the limits β_{cut} from the unphysical solutions of equations (9) and (10) as a result of $\alpha_0 = 0$; Open squares and circles: the limits β_{crit} set by the requirement of $T(c)/T_0 = 1$.

Fig. 4.— A comparison of the SZ profiles predicted by the isothermal gas distribution (dotted lines) and our derived radial distribution of intracluster gas from equations (9) and (10) (solid lines). Upper and lower panels correspond to the situations of $\beta = 2/3$ and $\beta = 1$ in Figure 1, respectively. The temperature profiles are shown by dashed lines. For clarity, the vertical scales for $\beta = 2/3$ (upper panel) have been multiplied by a factor of 10.
